

## Chapter 4

### Lecture 16

#### Engine characteristics – 4

##### Topics

- 4.3.3 Characteristics of a typical turboprop engine
- 4.3.4 Characteristics of a typical turbofan engine
- 4.3.5 Characteristics of a typical turbojet engines
- 4.4 Deducing output and SFC of engines where these characteristics are not available directly**
- 4.5 A note on choice of engines for different range of flight speeds**

##### 4.3.3 Characteristics of a turboprop engine

As noted earlier, in this engine, a major portion of the output is available at the propeller shaft (SHP) and a small fraction through the jet thrust ( $T_j$ ). Hence, the output is represented as:

$$THP = \eta_p \text{ SHP} + (T_j V_\infty / 1000) \quad (4.30)$$

where SHP = shaft horse power available at propeller shaft in kW,  $\eta_p$  = propeller efficiency and  $T_j$  = jet thrust

The total output of a turbo-prop engine, also called 'Equivalent shaft horse power (ESHP)', is defined as :

$$\text{ESHP} = \text{SHP} + \{T_j V_\infty / (0.8 \times 1000)\} \quad (4.31)$$

**Note** : (i) For the purpose of defining ESHP, the value of  $\eta_p$  is taken as 0.8 in Eq.(4.31). The ESHP and SHP are in kW.

(ii) Equation (4.31) would not be able to account for the contribution, to ESHP, of the thrust produced when the flight velocity ( $V$ ) is zero or the static condition. For this case and when  $V < 100$  knots (or 185 kmph), the convention is to define ESHP as follows (Ref.4.3, chapter 14).

$$\text{ESHP} = \text{SHP} + (T_j / 14.92) \quad (4.31a)$$

where ESHP and SHP are in kW and  $T_j$  is in N.

Flight dynamics-I  
Chapter IV

For example a turboprop engine developing SHP of 746 kW and jet thrust of 503 N, under sea level static condition, would have :

$$\text{ESHP} = 746 + (503/14.92) = 780 \text{ kW.}$$

Characteristics of a typical turbo-prop engine are shown in Fig.4.11. It is observed that the power output increases with flight speed. This increase is due to two factors viz. (a) the mass flow through the engine ( $\dot{m} = \rho A_i V_i$ ;  $A_i$  and  $V_i$  being the area of intake, and the velocity at the intake) increases with flight speed and (b) the pressure rise due to the deceleration of the flow in the inlet diffuser also increases with flight Mach number.

Figure 4.11 also shows the influence of ambient temperature on power output. It is observed that there is a significant fall in ESHP as the ambient temperature rises.

From the curves regarding fuel flow rate in Fig.4.11, the BSFC can be obtained at various speeds and altitudes as:

$$\text{BSFC} = (\text{Fuel flow/hr}) / \text{ESHP}$$

**Remark:**

Reference 3.9 Appendix E.3 gives performance curves for a large turboprop engine with sea level static power of 6500 HP. It may be noted that the 'Sea level static power' is the engine output at sea level at zero velocity. Reference 1.9, chapter 6 gives characteristics of an engine of around 1700 HP.

#### 4.3.4 Characteristics of typical turbofan engine

In the early turbofan engines the thrust output used to remain fairly constant with flight speed. In the modern turbofan engines the performance at low speeds and low altitudes (up to about 5 km) has been improved so that the ratio of the sea level static thrust and that (thrust) in high speed-high altitude flight is much higher than the early turbofan engines. The 'Sea level static thrust' is the engine output at  $M=0$  at sea level. Higher sea level static thrust helps in reducing the distance required for take-off. Figure 4.12 shows the variations of thrust with Mach number at different altitudes for an engine with bypass ratio of 4.9. The figure also shows the values of the specific fuel consumption (TSFC).

**Remark:**

Chapter 9 of Ref.3.22 gives the performance, in terms of non-dimensional parameters, for engines with bypass ratios of 3, 6.5, 8 and 13. The curves are also presented for take-off rating, climb rating and cruise rating. It may be added that the 'Take-off rating' is the engine output which can be availed for about 5 min. The engine can be run at 'Climb rating' for about half an hour and at 'Cruise rating' for long periods.

**4.3.5 Characteristics of typical turbojet engine**

The characteristics of a supersonic turbojet engine are shown in Figs.4.13a to d. It is observed that at subsonic speeds the thrust is fairly constant, but it increases considerably at supersonic speeds. This rise is due to increased ram pressure in the intake, as a result of the deceleration of the supersonic flow. The Mach

number at which the peak value of thrust occurs depends on the design of the engine.

Fig.4.13b Characteristics of engine in Fig.4.13a,  $h = 15000$  ft  
(With permission from Pratt and Whitney, East Hartford)

Fig.4.13c Characteristics of engine in Fig.4.13a,  $h = 30000$  ft  
(With permission from Pratt and Whitney, East Hartford)

Fig.4.13d Characteristics of engine in Fig.4.13a,  $h = 45000 \text{ ft}$   
(With permission from Pratt and Whitney, East Hartford)

**Remarks:**

- i) In Fig.4.13a to d the true airspeed is given in knots; one knot is equal to 1.852 kmph. Further, the speed of sound at  $h = 0, 15000', 30000'$  and  $45000'$  is respectively 661, 627, 589 and 574 knots.
- ii) Bypass supersonic turbofan engines are also being considered for supersonic flight. Reference 3.9, gives, in Appendix E, typical curves for an engine with sea level static thrust of 30000 lb (133 kN). Similarly Ref.4.5, chapter 8 also presents curves for an engine with 33000 lb (146.3 kN) sea level static thrust. Figures 4.13 a to d also indicate the values of specific fuel consumption (TSFC) and the air flow rate.
- iii) Figure 4.8b shows an afterburner duct between the turbine exit and the entry of the nozzle. The same figure also shows the fuel spray bars and the flame holder. An afterburner is used to increase the thrust output for a short duration. When the fuel is burnt in the afterburner, the temperature of the gases goes up and the thrust increases when these gases subsequently expand in the nozzle.

However, the specific fuel consumption also goes up considerably and the afterburner operation is resorted to only for a short duration like during take-off or transonic acceleration.

#### 4.4 Deducing output and SFC of engines where these characteristics are not available directly

The detailed information about engine performance (i.e. variations with altitude and flight velocity of the thrust (or power) and TSFC (or BSFC) is generally available only in a limited number of cases. To get the performance of an engine with other rating, scaling of the available data is carried out. For this purpose, the values of thrust(or power) of the engine, whose characteristics are known, are multiplied by a suitable factor which will bring the output of the existing engine equal to the output of the desired engine. It is assumed that the SFC values will be the same for the two engines. This kind of scaling is generally applicable for outputs within  $\pm 25\%$  of the output of the known engine (Ref.4.5, chapter 8).

#### 4.5 A note on choice of engines for different range of flight speeds

The topic of choice of engine for different types of airplanes is generally covered in airplane design. Here some salient points are mentioned to conclude the discussion on engines.

The following five criteria are used to select a power plant for a specific application.

**1.Overall efficiency ( $\eta_0$ )** : This quantity is the product of (a) thermodynamic cycle efficiency ( $\eta_t$ )(b) Combustion efficiency ( $\eta_c$ )(c) mechanical efficiency ( $\eta_m$ ) and (d) propulsive efficiency ( $\eta_p$ ). The thermodynamic efficiency depends on the thermodynamic cycle on which the engine operates. The details regarding estimation of  $\eta_t$  are available in books on thermodynamics. However, it is of the order of 40 to 50%. The combustion efficiency and mechanical efficiency would be around 95%. The propulsive efficiency of the propeller and gas turbine engines have been described in subsections 4.2.7, 4.2.8 and 4.3.2. It has been pointed out there that  $\eta_p$  depends on flight speed or Mach number.

The specific fuel consumption (SFC) is an indication of the overall efficiency. Based on Ref.3.9 chapter 3, it can be mentioned that the piston engine-propeller combination would have lowest SFC for Mach number (M) upto about 0.3. The turboprop engine would have lowest SFC in the range of Mach number from 0.3 to 0.6 which may extend to  $M \approx 0.7$  with the use of a transonic propeller. The high bypass ratio turbofans have lowest SFC between for  $M \approx 0.7$  to 1.0 and the low by-pass ratio ones between  $M \approx 1$  to 1.6 . Turbojets are more suited for  $M \approx 1.6$  to about 3.5 and ramjets later upto  $M \approx 8$  . It may be recapitulated that a ramjet engine requires another powerplant to bring it to Mach number of about 1.5.

## **2. Variation of thrust (or power) with flight speed and altitude:**

The shaft horse powers of piston engine and turboprop engine do not change significantly with flight speed. Consequently, the thrust outputs of these engines decrease significantly with flight speed or Mach number. The output of a turbofan engine decreases with Mach number, especially at low altitudes (Fig.4.12). The thrust of a jet engine is fairly constant at subsonic speeds but increases considerably at supersonic speeds (Fig.4.13 c & d). As regards the effect of flight altitude Eq.(4.1a) shows that for a piston engine  $(P/P_{sl}) = \sigma^{1.1}$  where  $\sigma$  is the density ratio and the suffix 'sl' denotes a quantity at sea level.

For a turbo-prop engine (from Ref 1.10 chapter 3),  $(P/P_{sl}) \approx \sigma^{0.7}$  . From Ref.3.15, chapter 3,  $(T/T_{sl})$  for turbofan and turbojet engines is also roughly proportional to  $\sigma^{0.7}$

## **3. Weight of the engine:**

The weight of the engine contributes to the gross weight of the airplane and hence it should be as low as possible. This quantity is indicated by the ratio  $W_{pp}/T$  or  $W_{pp}/BHP$ , where  $W_{pp}$  is the weight of the power plant. This ratio depends on the type of engine and the engine rating; it (ratio) decreases as the rating increases. Based on data in Ref.1.15, it can be mentioned that the weight per unit BHP for a piston engine is around 9N/kW for an engine with a rating of around 150 kW and about 6N/kW for a rating of around 500 kW. For a turboprop

engine  $W_{PP}/ESHP$  is around 2.9 N/kW for rating of 500 kW, 2.3 N/kW for a rating of 2500 kW and 1.4 N/kW for a rating of 7500 kW. For a turbofan engines the ratio  $W_{PP}/T$  could be around 0.25 N/N for a rating of around 100 kN and about 0.15 N/N for a rating of about 250 kN.

#### **4. Frontal area:**

The frontal area of an engine contributes to the parasite drag of the airplane. Hence, a lower frontal area is a desirable feature of the engine. For a given output the piston engine-propeller combination generally has the highest frontal area. Turboprop, turbofan and turbojet follow in the decreasing order of the frontal area.

#### **5. Other considerations :**

Gas turbine engines have mechanical simplicity as compared to a piston engine. However, gas turbine engines are costlier than the piston engines as some of the components of the gas turbine engines operate at higher temperature and RPM. This requires special materials and fabrication techniques.

Keeping these factors in view the different types of engine are used in the speed range/application as given in Table 4.3

<b>Type of engine</b>	<b>Speed / Mach number range</b>	<b>Application – airplanes in the following categories</b>
Piston engine-propeller combination	Upto 300 kmph	General aviation, trainer, agricultural and sports.
Turboprop	250 to 600 kmph; upto 750 kmph with advanced propeller	Short and medium range transport/cargo, aerial survey, feeder liner and executive transport.
Turbofan	M from 0.7 to 1.0	Medium and long range transports, cargo, maritime patrol, executive transport, jet trainer.
Turbojet	M from 1 to 3	Trainers, supersonic transport, fighter, interceptor, bomber.
Ramjet	M from 2 to 8	Intended for hypersonic transport.
